Parametric amplification of a superconducting plasma wave

S. Rajasekaran1,2, E. Casandru1,2, Y. Laplace1,2, D. Nicoletti1,2, G. D. Gu3, S. R. Clark4,5, D. Jaksch5,6 and A. Cavalleri1,2,5,*

Many applications in photonics require all-optical manipulation of plasma waves, which can concentrate electromagnetic energy on sub-wavelength length scales. This is difficult in metallic plasmas because of their small optical nonlinearities. Some layered superconductors support Josephson plasma waves, involving oscillatory tunnelling of the superfluid between capacitively coupled planes. Josephson plasma waves are also highly nonlinear, and exhibit striking phenomena such as cooperative emission of coherent terahertz radiation, superconductor-metal oscillations and soliton formation. Here, we show that terahertz Josephson plasma waves can be parametrically amplified through the cubic tunnelling nonlinearity in a cuprate superconductor. Parametric amplification is sensitive to the relative phase between pump and seed waves, and may be optimized to achieve squeezing of the order-parameter phase fluctuations or terahertz single-photon devices.

Cuprates are strongly anisotropic superconductors in which transport is made three-dimensional by Josephson tunnelling between the Cu–O planes. Tunnelling reduces the superfluid density in the direction perpendicular to the planes, and hence the frequency of the plasmon to below the average pair breaking gap. Weakly damped oscillations of the superfluid sustain transverse Josephson plasma waves (JPWs) that propagate along the planes.

Consider a complex superconducting order parameter in the rth Cu–O plane \( \psi(x, y, t) = |\psi(x, y, t)| \exp \theta(x, y, t) \), which depends on two in-plane spatial coordinates x and y and on time t. For a terahertz-frequency optical field polarized perpendicular to the planes, excitations above the superconducting gap are negligible and the modulus of the order parameter \(|\psi|\) (number of Cooper pairs) is nearly constant in space and time. Hence, the electrodynamics is dominated by the order-parameter phase \( \theta(x, y, t) \). Ignoring at first the spatial dependence of the phase, the local tunnelling strength can, from the Josephson equations, be expressed in terms of an equivalent inductance, L, which depends on the local interlayer phase difference \( \theta_{i\pm 1}(t) = \theta_i(t) - \theta_{i\pm 1}(t) \) as \( L(\theta_{i\pm 1}(t)) \sim I_\alpha / \cos(\theta_{i\pm 1}(t)) \), where \( I_\alpha \) is the inductance at equilibrium, \( h \) the reduced Planck’s constant, 2\( \epsilon \) the Cooper pair charge and \( I_\alpha \) the critical current. Denoting the capacitance of the Cu–O planes with a constant \( C \), we express the Josephson plasma resonance (JPR) frequency as \( \omega_{\text{JPR}} = 1 / (L(\theta_{i\pm 1}(t))C) \), where \( \omega_{\text{JPR}} \) is the equilibrium value. Correspondingly, the oscillator strength \( f \sim \omega_{\text{JPR}} \) for the plasma oscillations is also a function of the interlayer phase, and scales as \( f = f_0 \cos(\theta_{i\pm 1}(t)) \).

Figure 1 | Schematic representation of Josephson plasma waves. Schematic time-dependent representation of JPWs in the linear and nonlinear regime in the presence of a driving field \( E(t) = E_0 \sin(\omega_{\text{JPR}}t) \) polarized along the out-of-plane direction of a layered superconductor. Red arrows indicate the Josephson phase, while the corresponding oscillator strength is represented by the black circle area. A \( \text{JPW} \) in the linear regime consists of small-amplitude modulations of \( \theta_{i\pm 1} \) at constant oscillator strength \( f \sim \omega_{\text{JPR}} \).

In the nonlinear regime, the Josephson phase oscillates at \( \omega_{\text{JPR}} \), whereas \( f \) is modulated at \( 2\omega_{\text{JPR}} \).

The dependence of the oscillator strength \( f \) on the cosine of the superconducting phase corresponds to a third-order optical nonlinearity.

According to the second Josephson equation, the interlayer phase difference \( \theta_{i\pm 1}(t) \) advances in time with the time integral of the interlayer voltage drop, as \( \partial(\theta_{i\pm 1}(t))/\partial t = -2E/V \). For an optical field made resonant with the Josephson plasma frequency \( E(t) = E_0 \sin(\omega_{\text{JPR}}t) \), the interlayer phase oscillates as \( \theta_{i\pm 1}(t) = \theta_0 \cos(\omega_{\text{JPR}} t) \), where \( E_0 \) is the field amplitude and \( \theta_0 = (2\pi / \omega_{\text{JPR}}) E_0 \). (\( d \sim 1 \text{ nm} \) is the interlayer distance). This

implies that the oscillator strength \( f(t) = f_0 \cos(\theta_0 \cos(\omega_{\text{pump}} t)) \approx f_0 (1 - (\theta_0^2 + \theta_1^2 \cos(2\omega_{\text{pump}} t))/4) \) is modulated at a frequency \( 2\omega_{\text{pump}} \), whenever the field \( E_0 \) is large enough to make the phase excursion \( \theta_0 \) sizeable.

Figure 1 provides a pictorial representation of this physics. We plot a vector that represents both the phase difference \( \theta_{\text{diff}}(t) \) (vector angle) and the oscillator strength \( f(t) \) (vector length).

This picture shows how, for small driving fields, only \( \theta_{\text{diff}}(t) \) oscillates at the driving frequency \( \omega_{\text{pump}} \), whereas for larger fields these oscillations are accompanied by a \( 2\omega_{\text{pump}} \) modulation of the oscillator strength \( f(t) \).

Note also that the phenomena discussed above can be cast in terms of a Mathieu equation (see Supplementary Information 2). Thus, a \( 2\omega_{\text{pump}} \) modulation of the oscillator strength can serve as a pump for the parametric amplification of a second, weak plasma wave at frequency \( \omega_{\text{pump}} \). In this paper we demonstrate experimentally this effect in La\(_{1.95}\)Ba\(_{0.05}\)CuO\(_4\) (LBCO\(_{1.95}\)), a cuprate superconductor with the equilibrium JPR at \( \omega_{\text{pump}} \approx 0.5 \) THz.

Terahertz pulses, generated with a photoconductive antenna\(^{12}\), were used as a weak probe of JPRs (a schematic drawing of the measurement geometry is reported in Supplementary Information 1). A typical terahertz-field trace\(^{11}\) reflected by the sample is shown in Fig. 2a. Two different measurements are displayed: one taken below (red line) and the other one above (black line) the superconducting transition temperature \( T_\text{c} \approx 32 \) K. In the superconducting state, long-lived oscillations with \( \sim 2 \) ps period were observed on the trailing edge of the pulse, indicative of the JPR at \( \omega_{\text{pump}} \approx 0.5 \) THz. Figure 2b (solid red line) displays the corresponding
reflectivity edge in frequency domain. The solid lines in Fig. 2c,d are the complex dielectric permittivity $\varepsilon(\omega)$ and the loss function $L(\omega) = -\text{Im}(1/\varepsilon(\omega)) = e_L(\omega)/(\varepsilon_0 + e_L(\omega))^2$. $L(\omega)$ peaks at $\omega_{\text{loss}}$ where the real part of the dielectric permittivity, $\varepsilon_1(\omega)$, crosses zero.

These optical properties could be reproduced well by solving the wave equation in the superconductor in one dimension$^4$ (see Supplementary Information 3), which yields the space- and time-dependent order-parameter phase $\varphi_{\text{JS}}(x, t)$ (Fig. 2e) and the corresponding waves (negligible in linear response regime) of the oscillator strength $f = f_0 \cos(\varphi_{\text{JS}}(x, t))$ (Fig. 2f). The reflectivity, complex permittivity, and loss function (dashed lines in Fig. 2b-d, respectively) calculated from these simulations by solving the electromagnetic field at the sample surface$^5$, are in good agreement with the experimental data.

Amplification of a weak JPW like the one above (probe field) was achieved by mixing it with a second, intense pump field, which resonantly drove the Josephson phase to large amplitudes. Quasi-single cycle terahertz pulses, generated in LiNbO$_3$ with the tilted pulse front method$^{14}$ (yielding field strengths up to $\sim100\text{ kV cm}^{-1}$), were used to excite these waves in the nonlinear regime. The spectral content of these pulses extended between 0.2 and 0.7 THz, centred at the JPR frequency (see Supplementary Information 4). Note that the pump field strength used in this experiment exceeds the expected threshold to access the nonlinear regime, defined by $\delta = (2e E_0 d)/(\hbar \omega_{\text{th}}) \sim 1$ and corresponding in this material to field amplitudes $E_0 = (\hbar \omega_{\text{th}})/(2e d) \sim 20\text{ kV cm}^{-1}$.

In Fig. 3, we report the time-delay-dependent, spectrally integrated pump-probe response of LBCO$_{x-}$. Changes in the reflected probe field were measured at one specific probe sampling time ($t = t_0$) as a function of pump-probe time delay ($t$). For a system in which the optical properties are dominated by a single plasma resonance, the spectrally integrated response is proportional to the plasma oscillator strength $f$.

As shown in Fig. 3a-b, this integrated response exhibits a reduction of the signal and oscillations at a frequency $\sim 2\omega_{\text{th}}$. Note that the oscillation frequency did not depend on the pump electric field strength $E_p$, whereas the frequency reduced when the base temperature of the experiment was increased, consistent with the reduction of the equilibrium $\omega_{\text{th}}$ (see Supplementary Information 5 and 6). The effect completely disappeared at $T > T_c$. 

Figure 3 | Nonlinear JPWs in LBCO$_{x-}$. a. Normalized spectrally integrated pump-probe response $\Delta S_{\text{probe}}/S_{\text{probe}}(t, t_0 = 2\text{ ps})$. Experimental data are shown along with calculations based on the sine-Gordon equation in the nonlinear regime (displayed with a vertical offset). Dashed lines indicate an average reduction that accompanies the oscillations (see model). The reduction was subtracted through Fourier filtering ($\sim 0.2$ THz) to obtain the detail of the oscillations shown on the right. The signal buildup region affected by perturbed free induction decay is shaded in grey. b. Fourier transform of the extracted oscillations, showing a peak at $\sim 1$ THz. c,d. Phase $\varphi_{\text{JS}}(x, t)$ (c) and corresponding oscillator strength $f$ (d) induced by a strong terahertz pump field, as determined by numerically solving the sine-Gordon equation in the nonlinear regime. Horizontal dotted lines indicate the spatial coordinate $x$ at which the line cuts are displayed (lower panels).
Figure 4 | Amplification and suppression of plasma oscillations. 

a, $E_{\text{probe}}(t, \tau)$ traces measured by scanning the electro-optic sampling time $\tau$ at selected pump-probe delays $t = 0$ ps and $t = 2$ ps, respectively. Data are shown along with the same quantity measured at equilibrium (pump off). Plasma oscillations on the trailing edge of the pulse ($t \ll 2$ ps) are highlighted by thicker lines. Coloured shading indicates amplification (a) and suppression (b) of the JWPR amplitude.

Hence, the theoretically predicted $2\omega_{\text{pp}}$ modulation of the total oscillator strength $f$ (see above) is reproduced well by the data in Fig. 3. This response could also be simulated using the space- and time-dependent sine-Gordon equation (see Fig. 3c,d), yielding good agreement between experiment and theory (see blue lines in Fig. 3a,b).

Note that here we only analyse pump-probe delays $t \leq 0$ ps, because the response at the earliest times suffers from perturbed free induction decay\(^5\). This effect consists in the deformation of a coherent signal, which occurs when the pump strikes the sample during the oscillatory relaxation of the probe (for $t = 0$ ps in our case).

Selected time-domain probe traces measured before and after excitation are displayed in Fig. 4. Crucially, at specific time delays the probe field is amplified (Fig. 4a), whereas at other delays it is suppressed (Fig. 4b) with respect to that measured at equilibrium.

In Fig. 5 we report the time-delay-dependent and frequency-dependent loss function $L(t, \omega) = -\text{Im}(1/\tau(t, \omega)) = \epsilon_2(t, \omega)/(\epsilon_1(t, \omega) + \epsilon_2(t, \omega)^2)$, a quantity that peaks at the zero crossing of $\epsilon_1(t, \omega)$ and is always positive for a dissipative medium (that is, a medium with $\epsilon_2(t, \omega) > 0$). The experimental data of Fig. 5a show that, after excitation, $L(\omega)$ acquires negative values around $\omega_{\text{pp}}$ (red regions). This is indicative of a negative $\epsilon_2(t, \omega)$, and hence amplification. The effect is strong near zero pump-probe time delay, then disappears after $\sim 1$ ps, and is observed again periodically with a repetition frequency of $\sim 2\omega_{\text{pp}}$. The same effect appears also in the simulations (Fig. 5b), yielding periodic amplification at a repetition frequency of $2\omega_{\text{pp}}$.

In Supplementary Information 7 we report additional quantitative estimates of the degree of amplification. We include a negative absorption coefficient and a reflectivity larger than 1 at $\omega \approx \omega_{\text{pp}}$. The extracted values are $\alpha = (-0.090 \pm 0.003) \text{fs}^{-1}$ and $R = (1.042 \pm 0.008)$, respectively.

The data and simulations reported here demonstrate that terahertz JPWs can be parametrically amplified, exhibiting the expected sensitivity to the relative phase of strong and weak fields mixed in this process and the oscillatory dependence at twice the frequency of the drive.

Parametric amplification of terahertz light based on nonlinear optical techniques has already been shown in the past\(^5\). However, the physics demonstrated here extend beyond potential applications in photonics, directly leading to coherent parametric control of the superfluid in layered superconductors, and providing a means to manipulate the properties of the material or to probe them in new ways\(^5\).

Moreover, the ability to amplify a plasma wave could lead to terahertz single-phonon manipulation devices that may operate above $1$ K temperatures. These would exploit concepts that to date have been developed only at microwave frequencies and in the millikelvin regime\(^6-12\). Finally, the parametric phenomena discussed here can also potentially be used to squeeze\(^23,24\) the superfluid phase, and may lead to control of fluctuating superconductivity\(^25\), perhaps even over a range of temperatures above $T_s$ (refs 25,26).

Figure 5 | Time-delay-dependent and frequency-dependent loss function. 

a, b: Time-delay-dependent and frequency-dependent loss function $L(t, \omega)$ determined experimentally (a) and by numerically solving the sine-Gordon equation in nonlinear regime (b). Note that experimental and simulated $L(\omega)$ in the region between $t = -4$ ps and $t = -2$ ps have been multiplied by a factor of five to be better visualized with the other data.

Methods

Laser pulses with 100 fs duration and \(~\sim\) 5 mJ energy from a commercial Ti:Saph laser amplifier were split into two parts (92%, 7%, 1%). The most intense beam was used to generate strong-field terahertz pulses with energies up to \(~\sim\) 3 THz optical rectification in LiNbO₃, with the tilted pulse front technique. These were calibrated and then focused at normal incidence onto the sample (with polarization perpendicular to the CuO planes, that is, along the c axis) using a ZnTe lens and a parabolic mirror, with focal lengths of 150 mm and 75 mm, respectively. The pump spot diameter at the sample position was \(~\sim\) 2.5 mm. The pump field strength was calibrated with electro-optic sampling in a 0.2-mm-thick GaP crystal, yielding a maximum value of \(~\sim\) 100 kV cm\(^{-1}\) (see Supplementary Information 4).

The 7% beam was used to generate the terahertz probe pulses with a photoconductive antenna. These had a dynamic bandwidth of 0.1–3 THz, corresponding to a time resolution of \(~\sim\) 250 fs. The c-axis optical properties of the superconductor (both at equilibrium and throughout the pump-induced dynamics) were probed in reflection geometry, with a probe incidence angle of 45° and a spot diameter at the sample position of \(~\sim\) 2 mm. The reflected probe pulses were electro-optically sampled in a 1-mm-thick ZnTe crystal, using the remaining 2% of the 800 nm beam. This measurement procedure returned the quantity \(E_{\text{probe}}(t, r)\), with \(r\) being the pump–probe delay and \(t\) being the electro-optic sampling time coordinate.

The sample used in our experiment was a single crystal of \(\text{La}_{2-x}\text{Sr}_x\text{CuO}_4\) cut and polished along an ac oriented surface \(~\sim\) 3 \times 3 mm in size. Its equilibrium optical response in the superconducting state was determined by measuring the complex-valued \(E_{\text{probe}}(\omega)\) (pump off) both at \(T \leq T_c\) and \(T > T_c\), and by referencing it to the normal-state reflectivity measured in another crystal coming from the same batch of samples.

The spectrally integrated pump–probe traces of Fig. 3 were measured by scanning the pump–probe delay \(t\) at a fixed sampling time \(r = t\). This was chosen to be on the trailing edge of the pulse, where the JPR oscillations are present. Note that the observed dynamics, and in particular the 2\(\omega_{\text{JPR}}\) oscillations, did not depend significantly on the specific \(\varepsilon_r\) value at which the scan was performed.

The frequency and time-delay–dependent loss function of Fig. 5 (as well as all complex optical properties of the perturbed material) was determined by applying Fresnel equations\(^\text{25}\) to the pump-induced changes in the reflected electric field.

These were normalized by independently recording \(E_{\text{probe}}(t, r)\) in the presence and absence of the terahertz pump field. Note that there was no need to take into account any pump–probe penetration depth mismatch in the calculation.

In the simulations, the Josephson phase evolution \(\theta_{\text{JPR}}(x, t)\) was determined through the one-dimensional sine-Gordon equation:\(^\text{26}\)

\[
\frac{\partial^2 \theta_{\text{JPR}}(x, t)}{\partial t^2} = \frac{1}{\gamma} \frac{\partial \theta_{\text{JPR}}(x, t)}{\partial x} + \frac{\varepsilon}{c^2} \frac{\partial^2 \theta_{\text{JPR}}(x, t)}{\partial x^2} - \frac{\omega_{\text{JPR}}^2}{c^2} \sin \theta_{\text{JPR}}(x, t)
\]

\(\gamma\) being a damping constant, \(c\) the speed of light, \(\varepsilon\) the dielectric permittivity, and \(\omega_{\text{JPR}}\) the equilibrium JPR frequency. This equation was solved numerically, with the terahertz pump and probe fields overlapping at the vacuum/superconductor interface. For more details on this topic, we refer the reader to Supplementary Information 3.
